Gamm-ray bursts (GRBs) are thought to originate from collapsing massive stars or merging compact objects (such as neutron stars or black holes), and are associated with the formation of black holes in distant galaxies. GRB 130427A was detected by both the Large Area Telescope (LAT) and the Gamma-ray Burst Monitor (GBM) aboard the Fermi Gamma-ray Space Telescope. The LAT is a pair-conversion telescope that observes photons from 20 MeV to >300 GeV with a 2.4-steradian field of view (J). The GBM consists of 12 sodium iodide (NaI, 8 keV to 1 MeV) detectors and two bismuth germanate (BGO, 200 keV to 40 MeV) detectors, positioned around the spacecraft to view the entire un occulted sky (K).

In the standard model of GRBs, the blast wave that produces the initial, bright prompt emission later collides with the external material surrounding the GRB (the circumburst medium) and creates shocks [see, e.g., (3)]. These external shocks accelerate charged particles, which produce photons through synchrotron radiation. Until this burst, the high-energy emission from LAT-detected GRBs had been well described by this model, but GRB 130427A challenges this widely accepted model. In particular, the maximum possible photon energy predicted by this model is surpassed by the late-time high-energy photons detected by the LAT. The LAT detected high-energy γ-ray emission from this burst for almost 10 s, and a dim, broad peak at \( T_0 + 100 \) s.

The observations of the exceptionally bright gamma-ray burst (GRB) 130427A by the Large Area Telescope aboard the Fermi Gamma-ray Space Telescope provide constraints on the nature of these unique astrophysical sources. GRB 130427A had the largest fluence, highest-energy photon (95 GeV), longest γ-ray duration (20 hours), and one of the largest γ-ray emissions from this burst for almost 10 s, and a dim, broad peak at \( T_0 + 100 \) s. The Fermi LAT, operating in the regular survey mode, the GBM and RAPTOR detected bright optical emission from the GRB, peaking at a red-band magnitude of \( R = 7.03 \pm 0.03 \) around the GBM trigger time before fading to \( R = 10 \) about 80 s later (9). The Gemini-North observatory reported a red-shift of \( z = 0.34 \), and an underlying supernova has been detected (10). A total of 58 observatories have reported observations of this burst as of September 2013.

At the time of the GBM trigger, the GRB was 47.3° from the LAT boresight, well within the LAT field of view. The autonomous request point burst covered the burst to 20.1° from the LAT boresight, based on the position calculated by the GBM flight software. It remained in the LAT field of view for 715 s until it became occulted by Earth, reemerging from Earth occultation at \( T_0 + 3135 \) s. Within the first ~80 s after the trigger, the LAT detected more than 500 photons with energies greater than 100 MeV associated with the GRB; the previous record holder was GRB 090902B, with ~200 photons (11). In addition, the LAT detected 15 photons with energies greater than 10 GeV (versus only 3 photons for GRB 090902B). Using the LAT Low Energy (LLE) event selection (12), which considerably increases the LAT effective collecting area to lower-energy γ-rays down to 10 MeV (with adequate energy reconstruction down to 30 MeV), thousands of counts above background were detected between \( T_0 \) and \( T_0 + 100 \) s.

**Temporal Characteristics**

The temporal profile of the emission from GRB 130427A varies strongly with energy from \( 100 \) keV to \( \sim 100 \) GeV (Figs. 1 and 2). The GBM light curves consist of an initial peak lasting for a few seconds, a much brighter multipeaked emission episode lasting \( \sim 10 \) s, and a dim, broad peak at \( T_0 + 120 \) s, which fades to an undetectable level after \( \sim 300 \) s [also seen in the Swift light curve (7)].

The triggering pulse observed in the LLE (\( > 10 \) MeV) light curve is more sharply peaked than the NA- and BGO-detected emission at \( T_0 \).
The LLE light curve between $T_\text{b} - 4 + 7$ s and $T_\text{b} + 12$ s exhibits a multipeaked structure. Some of these peaks have counterparts in the GBM energy range, although the emission episodes are not perfectly correlated (e.g., the sharp spike in the LLE light curve at $T_\text{b} + 9.5$ s is not relatively bright in the GBM light curves) because of the spectral evolution with energy.

The LAT-detected emission, however, does not appear to be temporally correlated with either the LLE or GBM emission beyond the initial spike at $T_\text{b}$. Photons with energies greater than 1 GeV are first observed $\sim 10$ after $T_\text{b}$, after the brightest GBM emission has ended, consistent with a delayed onset of the high-energy emission (13). The delayed onset is not caused by a progressively increasing LAT acceptance due to slewing, because the slew started at $T_\text{b} + 3$ s. Instead, it reflects the true evolution of the GBM emission.

GRB spectra are generally well described by phenomenological models such as the Band function (13) or the smoothly broken power law (SBPL (16)). For the brightest LAT burst, the onset of the GBM emission is delayed with respect to the keV-MeV emission and can be fit by an additional power-law component (13). This additional component usually becomes significant while the keV-MeV emission is still bright.

For GRB 130427A, however, the extra power-law component becomes significant only after the GBM-detected emission has faded (Fig. 3). During the initial peak ($T_\text{b} - 0.1$ to $T_\text{b} + 4.5$ s), there are only a few LAT-detected photons, and the emission is well fit by an SBPL. For the brightest part of the burst ($T_\text{b} + 4.5$ s to $T_\text{b} + 11.5$ s), we did not use the GBM-detected emission because of the strong intrinsic systematic effects caused by extremely high flux (17). However, there are no photons with energies greater than 1 GeV in this 1 GeV time interval, and the energy spectrum above 30 MeV is well described by a single power law without a break (Fig. 3) (note that the LAT did not suffer from any pile-up issues).

Photons with energies greater than 1 GeV are detected in the last time interval ($T_\text{b} + 11.5$ s to $T_\text{b} + 33.0$ s), including a 73-GeV photon at $T_\text{b} + 19$ s. Unlike other bright LAT bursts, the LAT-detected emission from GRB 130427A appears to be temporally distinct from the GBM-detected emission, which suggests that the GeV and keV-MeV photons arise from different emission regions or mechanisms.

Temporally Extended High-Energy Emission
To characterize the temporally extended high-energy emission, we performed an unbinned maximum likelihood analysis of the LAT data for $E > 100$ MeV. We modeled the LAT photon spectrum as a power law with a spectral index $\alpha$ (i.e., the spectrum $N(E) \propto E^{-\alpha}$). We found evidence of spectral evolution during the high-energy emission. In contrast to another study (18) that used longer time intervals in the spectral fits, we found that the LAT ($E > 100$ MeV) spectrum of the GRB is well described by a power law at all times, but with a varying spectral index (17).

During the first pulse around $T_\text{b}$, emission at $E > 100$ MeV is faint and soft; the pulse contains only a few photons, and their energies are all $< 1$ GeV (Fig. 2). This is followed by a period during which there is no significant emission at $E > 100$ MeV, while the GBM emission is at its brightest. Starting around $T_\text{b} + 5$ s, emission at $E > 100$ MeV is detectable again but remains dim until $\sim T_\text{b} + 12$ s. The spectral index fluctuates between $\alpha = -2.5$ and $\alpha = -1.7$. At late times (longer than $T_\text{b} + 300$ s), we measured typical spectral indices of $\alpha = 2$, consistent with the indices of other LAT bursts (13). During the time intervals with the hardest spectra, the LAT observed the highest-energy photons—such as the 73-GeV photon at $T_1 + 19$ s and the record-breaking 95-GeV photon at $T_\text{b} + 244$ s—that severely restrict the possible mechanisms that could generate the high-energy afterglow emission (table S2).

The Greenland topography light curve is better fit by a broken power law than by a single power law. We found a break after a few hundred seconds, with the temporal index steepening from $-0.85 \pm 0.08$ to $-1.35 \pm 0.08$.
\(\chi^2/\text{df} = 36/19\) for a single power law, 16/17 for a broken power law. In contrast, the statistical uncertainties. For a single power-law fit to the energy flux light curve, we found a temporal index of \(-1.17 \pm 0.06\), consistent with other LAT bursts (13).

The GBM and Swift energy flux light curves are also shown in Fig. 2. The Swift X-Ray Telescope (XRT) began observing the burst at \(T_0 + 190\) s; the reported XRT + BAT (0.3 to 10 keV) light curve is a combination of XRT data and BAT-detected emission (15 to 150 keV) extrapolated down into the energy range of the XRT. The XRT + BAT light curve shows the unabsorbed flux in the range 0.3 to 10 keV (7). During the initial part of the burst, the GBM (10 keV to 10 MeV) light curve peaks earlier than both the XRT + BAT (0.3 to 10 keV) and LAT (>100 MeV) light curves. The GBM light curve peaks again at \(\sim T_0 + 120\) s [see also (7)], whereas the LAT light curve shows a sharp and hard peak at \(T_0 + 200\) s. The BAT + XRT light curve peaks again as well at the same time as the LAT light curve, but the peak is much broader.

**Interpretation**

The energetics of GRB 130427A place it among the brightest LAT bursts. For GRB 130427A, the fluence at 10 keV to 20 MeV measured with the GBM in the 400 s following \(T_0\) is \(\sim 4.2 \times 10^{-3}\) ergs cm\(^{-2}\). This value is within the uncertainties in the calibration of the GBM detectors contribute to a systematic error that we estimate to be less than 20%; the statistical uncertainty \([0.01 \times 10^{-3}\) ergs cm\(^{-2}\)] is negligible with respect to the systematic one (17). The fluence at \(>100\) MeV measured with the LAT in the 100 ks following \(T_0\) is \(7 (\pm 1) \times 10^{-4}\) ergs cm\(^{-2}\). The total LAT fluence is therefore \(\sim 20\%\) of the GBM fluence, similar to other bright LAT GRBs (13, 19).

For a total fluence at 10 keV to 100 GeV of \(4.9 \times 10^{-3}\) ergs cm\(^{-2}\), the total apparent isotropic \(\gamma\)-ray energy (i.e., the total energy release if there were no beaming) is \(E_{\gamma,\text{iso}} = 1.40 \times 10^{54}\) ergs, using a flat \(\Lambda\)CDM cosmology with reduced Hubble constant \(h = 0.71\) and dark energy density \(\Omega_{\Lambda} = 0.73\); this value implies a luminosity distance of \(1.8\) Gpc for \(z = 0.34\). This value of \(E_{\gamma,\text{iso}}\) is only slightly less than the values for other bright LAT hyperenergetic events, which include GRB 080916C, GRB 090902B, and GRB 090926A (19).

The emission region must be transparent against absorption by photon-photon pair production, which has a significant effect at the energies of the LAT-detected emission. Viable models of GRBs therefore require highly relativistic, jetted plasma outflows with bulk jet Lorentz factors \(\Gamma\) greater than \(\sim 100\) (20). The 73-GeV photon at \(T_0 + 19\) s (table S2) provides the most stringent limit on \(\Gamma\). Assuming that the variability time scale re-
reflects the size of the emitting region, and that the MeV and GeV emissions around the time of the 73-GeV photon at $T_0 + 10$ s are cospatial, the requirement that the optical depth due to $\gamma\gamma$ opacity be less than 1 then implies that the minimum bulk Lorentz factor is $\Gamma_{\text{min}} = 455 \pm 13$. Here, a SBPL fit to the GBM spectrum in the interval 11.5 to 33.0 s (table S1) and a minimum variability time scale of $0.04 \pm 0.01$ s are used (17). The cospatial assumption is, however, questionable given the different time histories in the MeV and GeV emission. Moreover, values of $\Gamma_{\text{min}}$ that are smaller by a factor of 2 to 3 can be realized for models with time-dependent $\gamma$-ray opacity in a thin-shell model (21).

The delayed onset of the LAT-detected emission with respect to the GBM-detected emission is an important clue to the nature of GRBs (13). For GRB 130427A, the LAT-detected emission becomes harder and more intense after the GBM-detected emission has faded (Fig. 3). This suggests that the GeV emission is produced later than the keV-MeV emission and in a different region. In particular, if the keV-MeV emission comes from interactions within the outflow itself, the GeV emission arises from the outflow's interactions with the circumburst medium.

![Fig. 2. Temporally extended LAT emission. Top: LAT energy flux (blue) and photon flux (red) light curves. The photon flux light curve shows a significant break at a few hundred seconds (red dashed line), whereas the energy flux light curve is well described by a single power law (blue dashed line). The 10 keV to 10 MeV (XRT, gray) and 0.3 to 10 keV (XRT + BAT, light blue) energy flux light curves are overplotted. The inset shows an expanded view of the first 50 s with a linear axes, with the photon flux light curve from the GBM (in units of $10^{-2}$ photons cm$^{-2}$ s$^{-1}$) plotted in gray for comparison. Middle: LAT photon index. Bottom: Energies of all the photons with probabilities $>90\%$ of being associated with the GRB (17). Solid circles correspond to the photon with the highest energy for each time interval.](image-url)
The explosive relativistic outflow of a GRB sweeps up and drives a shock into the circumburst medium. The medium could have, for instance, a uniform density $n_0$ (cm$^{-3}$) or a $n(r) \propto r^{-2}$ density profile resulting from the stellar wind of the type Ic supernova progenitor star associated with GRB 130427A (10). The LAT observations of GRB 130427A challenge the scenario in which the GeV photons are nonthermal synchrotron radiation emitted by electrons accelerated at the external forward shock (22, 23). In this model, the time of the brightest emission corresponds to the time $t_{\text{dec}}$ when most of the outflow energy is transferred to the shocked external medium. The Lorentz factor $\Gamma(t_{\text{dec}})$ of the shock outflow in the external medium at the deceleration time $t_{\text{dec}}$ is a lower limit for the initial bulk outflow Lorentz factor below $\Gamma_{0}$. Because a relativistic reverse shock would lower the shocked fluid Lorentz factor below $\Gamma_{0}$ and the engine time scale $t_{\text{GRB}}$ can be longer than $t_{\text{dec}}$, the deceleration time scale for an impulsive explosion. The activity of the central engine that produces the blast wave is revealed by the keV-MeV emission from particles accelerated at colliding-wind shocks. For GRB 130427A, the GeV emission starts to decay as a power law in time by $t = 20$ s (Fig. 2), and most of the keV-MeV radiation has subsided by $t = 12$ s (Fig. 1). The blast wave is in the self-similar deceleration phase at $t > t_{\text{dec}} = \max[t_{\text{dec}}, t_{\text{GRB}}]$,

where $T_{\text{GRB}}$ is the engine time scale (over which most of the outflow energy was released). Here, $t_{\text{dec}}(s) = \frac{2.4((E_{\gamma,0})^{10}/\text{erg})^{0.1}}{(t_{\text{GRB}}/10000)^{0.8}}$ for a uniform external medium, and $t_{\text{dec}} = \frac{6.3(E_{\gamma,0})^{10/3}/(0.1A_{\gamma}S_{\gamma}T_{\gamma}^{0.5})}{\text{erg}}$ for a stellar wind medium of density $\rho = AR^{-2}$, with $A = 5 \times 10^{28}$ g cm$^{-1}$. Most of the electron energy from GRB 130427A was radiated before $t = 12$ s, which suggests that $\Gamma_{0} \lesssim 12$ to 15 s. Defining $t_{1} = t_{\text{dec}}(10$ s) yields $t_{1} \approx 1$ to 2, which gives $\Gamma(t_{\text{dec}}) = 540(E_{\gamma,0}/n_{0}(\text{cm}^{-3}))^{1/10}$ for the uniform-density case, where $E_{\gamma,0} = E_{\gamma,0}(4 \times 10^{55} \text{ erg})$ is the isotropic energy release of the GRB. For a wind medium, $\Gamma(t_{\text{dec}}) = 450(E_{\gamma,0}/(A_{\gamma} n_{0}(\text{cm}^{-3})))^{1/10}$. Both values are close to the $\gamma\gamma$ opacity estimate of $\Gamma_{\text{ms}}$.

The presence of high-energy photons at times $t > t_{\text{dec}}$ (table S2) is compatible with these $\gamma$ rays having a synchrotron origin. Equating the electron energy loss time scale due to synchrotron radiation with the Larmor time scale for an electron in the shock results in the conserva-tive limit on the maximum synchrotron photon energy $E_{\text{max},\text{syn}} = \frac{2.77(16\pi n_{0}(\text{cm}^{-3}))^{1/8}}{\Gamma^{2}(1+z)} = 79(T_{\gamma}^{0.5})$ MeV, where $\Gamma_{0}$ is the fine-structure constant, $\langle 17 \rangle$. Using $\Gamma(t)$ derived by Blandford and McKee (24) in the adiabatic limit, we find that the maximum synchrotron photon energy $E_{\text{max},\text{syn}} < 7(E_{\gamma,0}/n_{0})^{1/3}(t/200 s)^{2/3}$ GeV, which agrees with results from integration over surfaces of equal arrival time in the self-similar regime (25), when a scaling factor of $27/16\pi$ is included (17). The presence of a 95-GeV photon at $T_{b} = 244$ s (Fig. 4 and table S2) is incompatible with a synchrotron origin even for conservative assumptions about Fermi acceleration. This conclusion holds for adiabatic and radiative external shocks in either uniform or wind media (see also (26)). The question of a wind or uniform-density model is not settled, but combined forward and reverse shock blast-wave model fits to the radio through x-ray emission from 0.67 days to 9.7 days after the GRB favor a wind medium (27), whereas inferences from Swift and LAT data suggest a uniform environment around GRB 130427A (7). Even in the extreme case where acceleration is assumed to operate on a time scale shorter than the Larmor time scale by a factor of 2, synchrotron radiation cannot account for the presence of high-energy radiation in the afterglow. Synchrotron emission above ~100 GeV is still possible, however, if an acceleration mechanism faster than the Fermi process is acting, such as magnetic reconnection [e.g., (28)].

The 95-GeV photon in the early afterglow and the 32-GeV photon at $T_{b} = 34.4$ s therefore cannot originate from lepton synchrotron radiation in the standard afterglow model with shock Fermi acceleration (Fig. 4). If the emission mechanism for the GeV photons is not synchrotron radiation, the highest-energy photons can still be

---

**Fig. 3. Time-resolved spectral models for the GBM- and LAT-detected emission.** Top: The combined NaI and BGO light curve from Fig. 1 (arbitrarily scaled) with the LAT-detected photons overplotted (same as the solid circles in Fig. 1). The time intervals are colored to correspond with the spectral models in the lower plot. The GBM data between 4.5 and 11.5 s are not included because they are substantially affected by pulse pile-up (17). Bottom: The models (thick lines) that best fit the data are plotted with 1σ error contours (thin dashed lines). Each curve ends at the energy of the highest-energy LAT photon detected within that time interval. An extra power law is statistically significant when fitting the data from $T_{b} = 11.5$ s to $T_{b} = 33.0$ s (17).
produced by lepton Compton processes. Synchrotron self-Compton (SSC) γ-rays, made when target synchrotron photons are Compton-scattered by the same jet electrons that emit the synchrotron emission, are unavoidable. SSC emission is expected to peak at TeV and higher energies during the prompt phase (although no GRB has been detected at TeV energies) and would cause the GeV light curve to flatten and the LAT spectrum to harden when the peak of the SSC component passes through the LAT waveband (29–31).

Such a feature may be seen in the light curves of GRB 090902B and GRB 090926A at 15 to 30 s after $T_0$ (13), but no such hardening or plateau associated with the SSC component is observed in the LAT light curve of GRB 130427A, although extreme parameters might still allow an SSC interpretation [see, e.g., (32)]. Except for the hard flare at $\tau \approx 250$ s and a possible softening at $\sim 3000$ s [and therefore not associated with a probable beaming break at $\approx 0.8$ days (7)], neither the integral photon nor energy-flux light curves in Fig. 2 show much structure or strong evidence for temporal or spectral variability from $r = 20$ s to $r = 1$ day. The NuSTAR observations (33) of the late-time hard x-ray afterglow also suggest that a single spectral component produces the emission from optical to multi-GeV energies. If this emission is indeed synchrotron radiation, then the standard afterglow shock model must be modified to account for the highest-energy photons detected by the LAT.

These considerations suggest that other extreme high-energy radiation mechanisms may be operative, such as external Compton processes. The most intense source of target photons is the powerful engine emissions, as revealed by the GBM and XRT prompt emission. A cocoon or remnant shell is also a possible source of soft photons, but unless the target photon source is extended and radiant, it would be difficult to model the nearly structureless LAT light curve over a long period of time. Given the similarity between the XRT and LAT light curves (Fig. 2), afterglow synchrotron radiation made by electrons accelerated at an external shock would also be the favored explanation for the LAT emission, but this is inconsistent with the detection of high-energy photons at late times.

The photon index of GRB 130427A, $\Gamma = -2$, is similar to those found in calculations of electromagnetic cascades created when the γ-ray opacity of ultrahigh energy (UHE, >100 TeV) photons in the jet plasma is large (34). An electromagnetic cascade induced by ultrarelativistic hadrons would be confirmed by coincident detection of neutrinos, but even for GRB 130427A with its neutrino limits, this would be confirmed by coincident detection of ultrahigh energy (UHE, >100 TeV) photons in the GeV light curve to flatten and the LAT spectrum to harden when the peak of the SSC component passes through the LAT waveband (29–31).

Fig. 4. Curves of maximum synchrotron photon energy. The black dots show the LAT detection times of photons with energies greater than 1 GeV and >90% probability of association with GRB 130427A. Adiabatic and radiative predictions for maximum synchrotron photon energy in uniform interstellar medium (ISM) and wind environments are plotted using the relations described in (17). Red and blue curves refer to the ISM and wind cases, respectively. The solid and dashed lines refer to the adiabatic and radiative cases with $\Gamma_0 = 1000$, and the dot-dashed and double dot-dashed lines represent the adiabatic case with $\Gamma_0 = 500$ and $\Gamma_0 = 2000$, respectively. The dotted lines show an extreme possibility where acceleration takes place on the inverse of the Larmor angular frequency, in the case of an adiabatic blast wave with $\Gamma_0 = 1000$. For cases with uniform external medium, $E_{\gamma} (10^{37} \text{erg}) / n (\text{cm}^{-3}) = 1$. The wind normalization was chosen to give the same value of $t_2$ for both wind and ISM cases. The vertical dotted lines show periods of Earth avoidance when the LAT could not observe GRB 130427A.
